## Abstract

We consider the linear stability of Hill's vortex with respect to axisymmetric perturbations. Given that Hill's vortex is a solution of a free-boundary problem, this stability analysis is performed by applying methods of shape differentiation to the contour dynamics formulation of the problem in a 3D axisymmetric geometry. This approach allows us to systematically account for the effect of boundary deformations on the linearized evolution of the vortex under the constraint of constant circulation. The resulting singular integro-differential operator defined on the vortex boundary is discretized with a highly accurate spectral approach. This operator has two unstable and two stable eigenvalues complemented by a continuous spectrum of neutrally-stable eigenvalues. By considering a family of suitably regularized (smoothed) eigenvalue problems solved with a range of numerical resolutions we demonstrate that the corresponding eigenfunctions are in fact singular objects in the form of infinitely sharp peaks localized at the front and rear stagnation points. These findings thus refine the results of the classical analysis by Moffatt & Moore (1978).

# 1 Introduction

Hill's vortex (Hill, 1894) is one of the few known analytical solutions of Euler's equations in three-dimensional (3D) space  $\Omega = \mathbb{R}^3$ . In the cylindrical polar coordinate system  $(x, \sigma, \phi)$ , it represents a compact axisymmetric region of azimuthal vorticity  $\boldsymbol{\omega} = [0, 0, \omega_\phi]$  moving with a constant velocity along the coordinate direction  $x$ . Hill's vortex is a particular (limiting) case of the Norbury-Fraenkel family of 3D axisymmetric vortex rings (Fraenkel, 1972; Norbury, 1973). Given the Stokes streamfunction  $\psi = \psi(x, \sigma)$  and the operator  $\mathcal{L} := \nabla \cdot (\frac{1}{\sigma} \nabla)$ , where  $\nabla := [\frac{\partial}{\partial x}, \frac{\partial}{\partial \sigma}]^T$  ("=" means "equal to by definition"), these flows satisfy the following system in the frame of reference moving with the translation velocity  $W$  of the vortex

$$\mathcal{L}\psi = -\sigma f(\psi) \quad \text{in } \Omega, \quad (1a)$$

$$\psi \rightarrow -\frac{1}{2}W\sigma^2 \quad \text{as } |\mathbf{x}| := \sqrt{x^2 + \sigma^2} \rightarrow \infty, \quad (1b)$$

where the vorticity function  $f(\psi)$  has the form

$$f(\psi) = \begin{cases} \mathcal{C}, & \psi > k \\ 0, & \psi \leq k \end{cases}, \quad (2)$$

in which  $\mathcal{C} \neq 0$  and  $k \geq 0$  are constants. System (1)–(2) therefore describes a compact region  $\mathcal{D}$  with azimuthal vorticity  $\omega := \omega_\phi$  varying proportionally to the distance  $\sigma$  from the flow axis embedded in a potential flow. The boundary of this region  $\partial\mathcal{D} := \{(x, \sigma, \phi) : \psi(x, \sigma) = k\}$  is a priori unknown and must be found as a part of the problem solution. System (1)–(2) thus represents a *free-boundary* problem and, as will become evident below, this property makes the study of the stability of solutions more complicated. For Hill's vortex the equilibrium shape of the boundary  $\partial\mathcal{D}$  has the form of a sphere with the flow described in the translating frame of reference by the streamfunction

$$\psi(x, \sigma) = \begin{cases} \frac{\mathcal{C}\sigma^2}{10}(a^2 - \sigma^2 - x^2), & \text{if } x^2 + \sigma^2 \leq a^2, \\ \frac{\mathcal{C}\sigma^2 a^2}{15} \left[ \frac{a^3}{(x^2 + \sigma^2)^{3/2}} - 1 \right], & \text{if } x^2 + \sigma^2 > a^2, \end{cases} \quad (3)$$

where  $a$  is the radius of the sphere. The components of the velocity field  $\mathbf{v} = [v_x, v_\sigma, v_\phi]^T$  can then be obtained as  $v_x = \frac{1}{\sigma} \frac{\partial \psi}{\partial \sigma}$ ,  $v_\sigma = -\frac{1}{\sigma} \frac{\partial \psi}{\partial x}$  and  $v_\phi = 0$ . Constant  $\mathcal{C}$  in (2), the translation velocity  $W$  and the vortex radius  $a$  are all linked through the relation (Wu *et al.*, 2006)

$$W = \frac{2}{15}\mathcal{C}a^2 \quad (4)$$

from which it follows that, for a fixed radius  $a$ , Hill's vortices represent a one-parameter family of solutions. To fix attention, unless indicated otherwise, hereafter we will set  $a = 1$ ,  $\mathcal{C} = -1$ , so that  $W = -2/15$  (i.e., the vortex is moving to the left).

Due to the presence of a sharp interface separating the vortical and potential flow regions, inviscid vortices in two and three dimensions are described by equations of the free-boundary type. In addition to making the process of finding (relative) equilibrium configurations more difficult, this also complicates their stability analysis. The main difficulty is that generic perturbations modify the domain on which the governing partial differential equations (PDEs) are defined together with their boundary conditions, an effect which must be taken into account in the derivation of the linearized evolution equations.

Most earlier approaches to studying stability of inviscid vortices have relied on methods adapted to specific problems. The stability of the simplest configurations, namely the Rankine and Kirchhoff vortices, was first investigated, respectively, by Kelvin (1880) and Love (1893). Further insights about these problems were provided by the studies of Moore & Saffman (1971); Baker (1990); Guo *et al.* (2004); Mitchell & Rossi (2008). The linear stability of more complex vortex configurations, such as polygonal arrays of corotating vortices and translating vortex pairs, was investigated by Dritschel (1985, 1990, 1995), see also Dritschel & Legras (1991). A noteworthy feature of their approach is that they also used a *continuous* perturbation equation independent of a particular discretization employed to obtain the equilibrium solution. The linear stability of the so-called V-states (Wu *et al.*, 1984), corotating vortex patches and infinite periodic arrays of vortices was investigated in detail by Kamm (1987), see as well Saffman (1992). This approach was based on the representation of the solution in terms of the Schwarz function, and required discretization and numerical differentiation in order to obtain the perturbation equation. A discrete form of the perturbation equation was also used by Elcrat *et al.* (2005) in their investigation of the linear stability of vortices in a symmetric equilibrium with a circular cylinder and a free stream at infinity. Another family of approaches is based on variational energy arguments going back to Kelvin. They were initially investigated by Dritschel (1985); Saffman & Szeto (1980); Dritschel (1988); Fukumoto & Moffatt (2008), and were more recently pursued by Luzzatto-Fegiz & Williamson (2010, 2012). They rely on global properties of the excess energy vs. velocity impulse diagrams and provide partial information about the linear stability properties without the need to actually perform a full linear stability analysis.

A systematic and general approach to the study of stability of inviscid vortices was recently developed by the present authors (Elcrat & Protas, 2013). It is defined entirely in the continuous setting and relies on the “shape-differential” calculus (Delfour & Zolésio, 2001) for a rigorous treatment of boundary deformations and their effect on the linearized evolution. A starting point of this approach is an equilibrium configuration (a “fixed point”) of a contour-dynamics formulation of the flow evolution (Pullin, 1992). The boundary of the vortex region is then perturbed in the normal direction and the contour-dynamics equations are linearized, via shape differentiation, around the equilibrium configuration. As a result, a singular integro-differential equation is obtained for the linearized evolution of the normal perturbation. It is defined on the vortex boundary and the associated eigenvalue problem encodes information about stability. In contrast to most of the earlier approaches mentioned above, this formulation is general,

in the sense that it is not tailored to a particular vortex configuration and does not involve any simplifications (such as boundary conditions satisfied only approximately or numerical differentiation). It also does not restrict the imposed perturbations to be irrotational. Therefore, the obtained singular integro-differential equation may be considered a vortex-dynamics analogue of the Orr-Sommerfeld equation used to study the stability of viscous parallel shear flows (Drazin & Reid, 2004). It was shown by Elcrat & Protas (2013) that the classical stability analyses of Kelvin (1880) and Love (1893) can be derived as special cases from the proposed framework. In situations in which the eigenvalue problem is not analytically tractable, the integro-differential equation can be approximated numerically with spectral accuracy (Elcrat & Protas, 2013).

As regards the stability of Hill’s vortex, which is the subject of the present study, Moffatt & Moore made the following remark in their 1978 paper: “... *it is rather remarkable that its stability characteristics have not been investigated in detail*”. In the light of this comment made more than 35 years ago, it is perhaps even more remarkable that important aspects of this problem in fact still remain open. More precisely, only partial results are available corresponding to the linearized response of Hill’s vortex to a perturbation applied to its boundary. Moffatt & Moore (1978) studied the response to axisymmetric perturbations by analyzing an approximate equation for the evolution of the vortex boundary (a similar approach had been developed earlier by Bliss (1973)). Their key finding was that the perturbations evolve towards the shape of a sharp “spike” localized at the rear stagnation point and directed into or out of the vortex depending on the form of the initial perturbation. The authors also noted the absence of any oscillatory components in the vortex response. These observations were confirmed by the computations of Pozrikidis (1986) who studied the evolution of disturbances well into the nonlinear regime. He demonstrated that the spike-like deformation of the vortex boundary arising from the linear instability leads to a significant fluid detrainment or entrainment over longer times. The response of Hill’s vortex to general, non-axisymmetric perturbations was studied using approximate techniques based on expansions of the flow variables in spherical harmonics and numerical integration by Fukuyu *et al.* (1994); Rozi (1999). Their main findings were consistent with those of Moffatt & Moore (1978), namely, that perturbations of the vortex boundary develop into sharp spikes whose number depends on the azimuthal wavenumber of the perturbation. A number of investigations (Lifschitz, 1995; Rozi & Fukumoto, 2000; Hattori & Hijiya, 2010) studied the stability of Hill’s vortex with respect to short-wavelength perturbations applied locally and advected by the flow in the spirit of the WKB approach (Lifschitz & Hameiri, 1991). These analyses revealed the presence of a number of instability mechanisms, although they are restricted to the short-wavelength regime. In this context we also mention the study by Llewellyn Smith & Ford (2001) who considered the linear response of the compressible Hill’s vortex to acoustic waves.

Our present investigation attempts to complete the picture by performing, for a first time, a *global* spectral stability analysis of Hill’s vortex with respect to axisymmetric perturbations. We provide numerical evidence based on highly accurate computations that this problem is not, in fact, well posed in the sense that the eigenfunctions are

“distributions” (i.e., they are not continuous functions of the arclength). By considering a sequence of suitably regularized problems and using methods of harmonic analysis it is demonstrated that the eigenfunctions corresponding to, respectively, the unstable and stable modes have the form of infinitely sharp spikes localized at the rear and front stagnation points. These findings thus refine the conclusions from the earlier approximate computations of Moffatt & Moore (1978); Fukuyu *et al.* (1994); Rozi (1999). We also show that the discrete spectrum corresponding to the stable and unstable modes is complemented by a continuous spectrum of equally non-smooth neutrally-stable eigenmodes. The structure of the paper is as follows: in the next section we use methods of the shape calculus to derive the stability equation; in §3 we describe and validate the numerical approach, whereas computational results are presented in §4; the results are discussed in §5 and final comments are deferred to §6.

## 2 Derivation of the Stability Equation

In this section we first provide details of the contour-dynamics formulation in the 3D axisymmetric geometry which is the basis of our approach. Then, methods of shape calculus are used to derive an integro-differential equation characterizing the stability of Hill’s vortex. Finally, we discuss some properties of this equation. Hereafter  $\mathcal{A}$  will denote the projection of the axisymmetric vortex region  $\mathcal{D}$  onto the meridional plane  $\{x, \sigma\}$ .

The formalism of contour dynamics is a convenient way to study the evolution of inviscid flows with piecewise smooth vorticity distributions (Pullin, 1992). Given a time-dependent region  $\mathcal{A}(t)$ , where  $t$  is time, its evolution can be studied by tracking the points  $\mathbf{y}(t)$  on its boundary  $\partial\mathcal{A}(t)$  via the equation

$$\frac{d\mathbf{y}(t)}{dt} = \mathbf{v}(\mathbf{y}(t)) = \mathcal{C} \int_{\partial\mathcal{A}(t)} \mathbf{K}(\mathbf{y}(t), \mathbf{y}') ds_{\mathbf{y}'}, \quad \forall \mathbf{y}(t) \in \partial\mathcal{A}(t), \quad (5)$$

where  $\mathbf{K}(\mathbf{y}(t), \mathbf{y}')$  is a suitable Biot-Savart kernel,  $\mathbf{y}$  and  $\mathbf{y}'$  are defined in the absolute frame of reference and  $ds_{\mathbf{y}'}$  is an arclength element of the vortex boundary in the meridional plane. An equilibrium shape of the vortex boundary, denoted  $\partial\mathcal{A}$  (without the argument  $t$ ), can be characterized by transforming the coordinates to the translating frame of reference  $\mathbf{x}(t) := \mathbf{y}(t) - Wt \mathbf{e}_x$  and considering the normal component of equation (5)

$$\mathbf{n}_{\mathbf{x}} \cdot \frac{d\mathbf{x}(t)}{dt} = \mathcal{C} \mathbf{n}_{\mathbf{x}} \cdot \left[ \int_{\partial\mathcal{A}} \mathbf{K}(\mathbf{x}(t), \mathbf{x}') ds_{\mathbf{x}'} - W \mathbf{e}_x \right] = 0, \quad (6)$$

where  $\mathbf{n}_{\mathbf{x}}$  denotes the unit vector normal to the contour  $\partial\mathcal{A}$  at the point  $\mathbf{x}$  (hereafter we will use the convention that a subscript on a geometric quantity will indicate where this quantity is evaluated). Since we have  $\mathbf{x}(0) = \mathbf{y}(0)$ , the arguments of the kernel  $\mathbf{K}$  in (6) can be changed to  $\mathbf{x}$  and  $\mathbf{x}'$ . Equation (6) expresses the vanishing of the normal velocity component on the vortex boundary in relative equilibrium. Since the equilibrium shape

of the boundary  $\partial\mathcal{A}$  is in general a priori unknown, relation (6) reveals the free-boundary aspect of the problem. The Biot-Savart kernel was derived by Wakelin & Riley (1996) with an alternative, but equivalent, formulation also given by Pozrikidis (1986). Here we will use this kernel in the form rederived and tested by Shariff *et al.* (2008)

$$\mathbf{K}(x \mathbf{e}_x + \sigma \mathbf{e}_\sigma, x' \mathbf{e}_x + \sigma' \mathbf{e}_\sigma) = [(x' - x) G(x, x', \sigma, \sigma') \cos \theta' - \sigma H(x, x', \sigma, \sigma') \sin \theta'] \mathbf{e}_x + \sigma' H(x, x', \sigma, \sigma') \cos \theta' \mathbf{e}_\sigma, \quad (7)$$

where

$$G(x, x', \sigma, \sigma') := \frac{\sigma'}{\pi \sqrt{A+B}} K(\tilde{r}),$$

$$H(x, x', \sigma, \sigma') := \frac{1}{2\pi\sigma} \left[ \frac{A}{\sqrt{A+B}} K(\tilde{r}) - E(\tilde{r}) \sqrt{A+B} \right]$$

in which

$$A := (x - x')^2 + \sigma^2 + \sigma'^2, \quad B := 2\sigma\sigma', \quad \tilde{r} := \sqrt{\frac{2B}{A+B}},$$

whereas  $\theta'$  denotes the polar angle of the point  $\mathbf{x}'$ , i.e.,  $\cos \theta' = x'/\sqrt{x'^2 + \sigma'^2}$  and  $\sin \theta' = \sigma'/\sqrt{x'^2 + \sigma'^2}$ , and  $K(\tilde{r})$  and  $E(\tilde{r})$  are the complete elliptic integrals of the first and second kind, respectively (Olver *et al.*, 2010). We note that  $\tilde{r} \rightarrow 1$  as  $x' \rightarrow x$  and  $\sigma' \rightarrow \sigma$ , and at  $\tilde{r} = 1$  function  $K(\tilde{r})$  has a logarithmic singularity (more details about the singularity structure of kernel (7) will be provided below).

In addition to the circulation, impulse and energy conserved by all classical solutions of Euler's equations, axisymmetric inviscid flows also conserve Casimirs  $\iint_{\mathcal{A}(t)} \Phi(\omega/\sigma) \sigma d\mathcal{A}$ , where  $\Phi : \mathbb{R} \rightarrow \mathbb{R}$  is an arbitrary function with sufficient regularity (Mohseni, 2001). Since circulation is particularly important from the physical point of view, we will focus on stability analysis with respect to perturbations preserving this quantity, which is the same approach as was also taken by Moffatt & Moore (1978). Circulation  $\Gamma$  of the flow in the meridional plane is defined as

$$\Gamma := \iint_{\mathcal{A}(t)} \omega d\mathcal{A} \quad (8)$$

and can be also viewed as the Casimir corresponding to  $\Phi(\xi) = \xi$ . We add that, since the flows considered here have the property  $\omega = \mathcal{C}\sigma$ , cf. (1)–(2), conservation of circulation (8) implies the conservation of the volume of the vortical region.

Following the ideas laid out by Elcrat & Protas (2013), we introduce a parameterization of the contour  $\mathbf{x} = \mathbf{x}(t, s) \in \partial\mathcal{A}(t)$  in terms of its arclength  $s$ . We will also adopt the convention that the superscript  $\epsilon$ , where  $0 < \epsilon \ll 1$ , will denote quantities corresponding to the perturbed boundary, so that  $\mathbf{x} = \mathbf{x}^\epsilon|_{\epsilon=0}$  and  $\mathbf{n}_\mathbf{x} = \mathbf{n}_\mathbf{x}^\epsilon|_{\epsilon=0}$  are the quantities corresponding to the (relative) equilibrium. Then, points on the perturbed vortex boundary can be represented as follows

$$\mathbf{x}^\epsilon(t, s) = \mathbf{x}(s) + \epsilon r(t, s) \mathbf{n}_\mathbf{x}(s), \quad (9)$$

where  $r(t, s)$  represents the “shape” of the perturbation. We note that, without affecting the final result,  $\mathbf{n}_\mathbf{x}(s)$  in the last term in (9) could be replaced with its perturbed counterpart  $\mathbf{n}_{\mathbf{x}^\epsilon}(t, s)$ . Using equation (5) we thus deduce

$$\mathbf{n}_{\mathbf{x}^\epsilon} \cdot \frac{d\mathbf{x}^\epsilon(t)}{dt} = \mathbf{n}_{\mathbf{x}^\epsilon} \cdot \mathbf{v}^\epsilon(\mathbf{x}^\epsilon(t)) = \mathcal{C} \mathbf{n}_{\mathbf{x}^\epsilon} \cdot \left[ \int_{\partial A^\epsilon(t)} \mathbf{K}(\mathbf{x}^\epsilon(t), \mathbf{x}') ds_{\mathbf{x}'} - W \mathbf{e}_x \right], \quad (10)$$

from which the equilibrium condition (6) is obtained by setting  $\epsilon = 0$ . The perturbation equation is obtained by linearizing relation (10) around the equilibrium configuration characterized by (6) which is equivalent to expanding (10) in powers of  $\epsilon$  and retaining the first-order terms. Since equation (10) involves perturbed quantities defined on the perturbed vortex boundary  $\partial A^\epsilon(t)$ , the proper way to obtain this linearization is using methods of the shape-differential calculus (Delfour & Zolésio, 2001). Below we state the main results only and refer the reader to our earlier study (Elcrat & Protas, 2013) for details of all intermediate transformations. Shape-differentiating the left-hand side (LHS) of relation (10) and setting  $\epsilon = 0$  we obtain

$$\frac{d}{d\epsilon} \left[ \mathbf{n}_{\mathbf{x}^\epsilon} \cdot \frac{d\mathbf{x}^\epsilon(t)}{dt} \right] \Big|_{\epsilon=0} = \frac{\partial r}{\partial t}. \quad (11)$$

As regards the right-hand side (RHS) in (10), we obtain

$$\begin{aligned} \frac{d}{d\epsilon} \left\{ \mathcal{C} \mathbf{n}_{\mathbf{x}^\epsilon} \cdot \left[ \int_{\partial A^\epsilon(t)} \mathbf{K}(\mathbf{x}^\epsilon(t), \mathbf{x}') ds_{\mathbf{x}'} - W \mathbf{e}_x \right] \right\} \Big|_{\epsilon=0} = \\ = -\frac{\partial r}{\partial s} \mathbf{v}_0 \cdot \mathbf{t}_\mathbf{x} + \mathcal{C} r(s) \mathbf{n}_\mathbf{x} \cdot \int_{\partial \mathcal{A}} \frac{\partial \mathbf{K}}{\partial n_\mathbf{x}} ds' + \mathcal{C} \mathbf{n}_\mathbf{x} \cdot \int_{\partial \mathcal{A}} \left[ \frac{\partial \mathbf{K}}{\partial n_{\mathbf{x}'}} + \varkappa_{\mathbf{x}'} \mathbf{K} \right] r(s') ds', \end{aligned} \quad (12)$$

where  $\mathbf{t}_\mathbf{x}$  is the unit tangent vector and  $\varkappa_\mathbf{x}$  the curvature of the contour  $\partial \mathcal{A}$  (in the present case, with the contour  $\partial \mathcal{A}$  given by a half-circle of unit radius,  $\varkappa \equiv 1$ ). The orientation of the unit vectors  $\mathbf{t}_\mathbf{x}$  and  $\mathbf{n}_\mathbf{x}$ , and the sign of the curvature  $\varkappa_\mathbf{x}$  satisfy Frenet’s convention. As explained by Elcrat & Protas (2013), the three terms on the RHS of (12) represent the shape-sensitivity of the RHS of (10) to perturbations (9) applied separately to the normal vector  $\mathbf{n}_\mathbf{x}$ , the evaluation point  $\mathbf{x}$  and the contour  $\partial \mathcal{A}$  over which the integral is defined. Since the flow evolution is subject to constraint (8), this will restrict the admissible perturbations  $r$ . Indeed, noting that  $\omega = \mathcal{C}\sigma$ , cf. (1)–(2), and shape-differentiating relation (8) we obtain the following condition (Elcrat & Protas, 2013)

$$\int_{\partial \mathcal{A}} \sigma r(s') ds' = 0 \quad (13)$$

restricting the class of admissible perturbations to those which do not modify the circulation (8), although the vorticity may change locally (analogous conditions can be obtained when the perturbations are constructed to preserve other integral invariants mentioned above). In the case of Hill’s vortex with the assumed parameter values, the

equilibrium shape of the vortex boundary is given by the sphere of unit radius, so that  $\partial\mathcal{A} = \{(x, \sigma) : x^2 + \sigma^2 = 1\}$ . In such case the arclength coordinate  $s$  reduces to the polar angle  $\theta \in [0, \pi]$ , so that  $x = \cos \theta$  and  $\sigma = \sin \theta$ . Therefore, below we will use  $\theta$  as our independent variable.

Combining (11)–(13) and replacing the line integrals with the corresponding definite ones we finally obtain the perturbation equation

$$\frac{\partial r}{\partial t} = -\frac{\partial r}{\partial \theta} \mathbf{v}_0 \cdot \mathbf{t}_\theta + \mathcal{C} r(\theta) \int_0^\pi I_2(\theta, \theta') d\theta' + \mathcal{C} \int_0^\pi I_1(\theta, \theta') r(\theta') d\theta' \quad (14a)$$

$$:= (\mathcal{L}r)(\theta)$$

$$\text{subject to: } \int_0^\pi \sin \theta' r(\theta') d\theta' = 0, \quad (14b)$$

where  $\mathcal{L}$  denotes the associated linear operator and

$$I_1(\theta, \theta') := \mathbf{n}_\theta \cdot \left[ \frac{\partial \mathbf{K}(\theta, \theta')}{\partial n_{\theta'}} + \varkappa_{\theta'} \mathbf{K}(\theta, \theta') \right] = [-3 \cos \theta + 5 \cos \theta'] \mathcal{Q}(\theta, \theta'), \quad (15a)$$

$$I_2(\theta, \theta') := \mathbf{n}_\theta \cdot \frac{\partial \mathbf{K}(\theta, \theta')}{\partial n_\theta} = [\cos \theta + \cos \theta'] \mathcal{Q}(\theta, \theta') \quad (15b)$$

in which

$$\mathcal{Q}(\theta, \theta') := \frac{[\cos \theta' \sin(-\theta + \theta') + \sin \theta - \sin \theta'] K(\tilde{R}) + \sin \theta' [\cos \theta - \cos \theta']^2 E(\tilde{R})}{2\pi [\cos(\theta - \theta') - 1] \sqrt{2 - 2 \cos(\theta - \theta')}},$$

$$\tilde{R} := \sqrt{[\cos(-\theta + \theta') - \cos(\theta + \theta')] / [1 - \cos(\theta + \theta')]}.$$

As regards the singularities of the kernels, one can verify by inspection that

$$\forall \theta \in (0, \pi) \quad \lim_{\theta' \rightarrow \theta} \mathbf{n}_\theta \cdot \mathbf{K}(\theta, \theta') = 0, \quad (16a)$$

$$\lim_{\theta' \rightarrow \theta} \frac{\mathbf{t}_\theta \cdot \mathbf{K}(\theta, \theta')}{\ln |\theta - \theta'|} = -\frac{1}{2\pi} \sin \theta, \quad (16b)$$

$$\lim_{\theta' \rightarrow \theta} \frac{I_1(\theta, \theta')}{\ln |\theta - \theta'|} = -\frac{1}{2\pi} \cos \theta, \quad (16c)$$

$$\lim_{\theta' \rightarrow \theta} \frac{I_2(\theta, \theta')}{\ln |\theta - \theta'|} = \frac{1}{2\pi} \cos \theta. \quad (16d)$$

The singularities of the kernels  $I_1(\theta, \theta')$  and  $I_2(\theta, \theta')$  vanish at  $\theta = 0$  and  $\theta = \pi$ . Properties (16a)–(16d) will be instrumental in achieving spectral accuracy in the discretization of system (14).

Equation (14a) is a first-order integro-differential equation and as such would in principle require only one boundary condition. However, since the kernel (7) is obtained via averaging with respect to the azimuthal angle  $\phi$  (due to the axisymmetry assumption,

see Shariff *et al.* (2008)), the different terms and integrands in equation (14a) exhibit the following reflection symmetries

$$\forall \theta \in [0, \pi] \quad (\mathbf{v}_0 \cdot \mathbf{t})_\theta = -(\mathbf{v}_0 \cdot \mathbf{t})_{-\theta}, \quad (17a)$$

$$I_1(\theta, \theta') = -I_1(-\theta, -\theta'), \quad (17b)$$

$$I_2(\theta, \theta') = -I_2(-\theta, -\theta') \quad (17c)$$

indicating that equation (14a) is invariant with respect to the change of the independent variable  $\eta = -\theta \in [-\pi, 0]$ . This means that when equation (14a) is considered on an extended periodic domain  $[-\pi, \pi]$  subject to *even* initial data  $r(0, \theta) = r(0, -\theta)$ ,  $\theta \in (0, \pi)$ , its solution will also remain an even function of  $\theta$  at all times, i.e.,  $r(t, \theta) = r(t, -\theta)$ ,  $t > 0$ . In particular, *if* they are smooth enough, these solutions will satisfy the symmetry conditions

$$\left. \frac{\partial^{2k-1} r}{\partial \theta^{2k-1}} \right|_{\theta=0} = \left. \frac{\partial^{2k-1} r}{\partial \theta^{2k-1}} \right|_{\theta=\pi} = 0, \quad k = 1, 2, \dots \quad (18)$$

Thus, system (14) with even initial data (which is consistent with the axisymmetry assumption) and subject to boundary conditions (18) is *not* an over-determined problem. These observations will be used in the next section to construct a spectral discretization of equation (14a).

After introducing the ansatz

$$r(t, \theta) = e^{i\lambda t} u(\theta) + C.C., \quad (19)$$

where  $i := \sqrt{-1}$  and  $\lambda \in \mathbb{C}$ , system (14) together with the boundary conditions (18) takes the form of a constrained eigenvalue problem

$$i \lambda u(\theta) = (\mathcal{L}u)(\theta), \quad \theta \in (0, \pi) \quad (20a)$$

$$\text{subject to: } \left. \frac{\partial^{2k-1} u}{\partial \theta^{2k-1}} \right|_{\theta=0} = \left. \frac{\partial^{2k-1} u}{\partial \theta^{2k-1}} \right|_{\theta=\pi} = 0, \quad k = 1, 2, \dots, \quad (20b)$$

$$\int_0^\pi \sin \theta' u(\theta') d\theta' = 0, \quad (20c)$$

where the operator  $\mathcal{L}$  is defined in (14a). The eigenvalues  $\lambda$  and the eigenfunctions  $u$  characterize the stability of Hill's vortex to axisymmetric perturbations.

### 3 Numerical Approach

In this section we describe the numerical approach with a focus on the discretization of system (20) and the solution of the resulting algebraic eigenvalue problem. We will also provide some details about how this approach has been validated. We are interested in achieving the highest possible accuracy and, in principle, eigenvalue problems

for operators defined in the continuous setting on one-dimensional (1D) domains can be solved with machine precision using `chebfun` (Driscoll *et al.*, 2014). However, at present, `chebfun` does not have the capability to deal with singular integral operators such as  $\mathcal{L}$ . We have therefore implemented an alternative hybrid approach relying on a representation of the operator  $\mathcal{L}$  in a trigonometric basis in which kernel singularities are treated analytically and `chebfun` is used to evaluate the remaining definite integrals with high precision.

The eigenfunctions  $u$  are approximated with the following truncated series

$$u(\theta) \approx u^N(\theta) := \sum_{k=0}^{N-1} \alpha_k \cos k\theta, \quad (21)$$

where  $\alpha_0, \dots, \alpha_{N-1} \in \mathbb{R}$  are unknown coefficients, which satisfies exactly the boundary conditions (18). The interval  $[0, \pi]$  is discretized with equispaced grid points

$$\theta_j = \frac{\pi}{N-1}j, \quad j = 0, \dots, N-1 \quad (22)$$

(both endpoints are included in the grid). After substitution of ansatz (21), equation (20a) is collocated on grid (22), whereas constraint (20c) takes the form

$$\sum_{k=0}^{N-1} \alpha_k \int_0^\pi \sin \theta' \cos k\theta' d\theta' = 0 \quad (23)$$

in which the integrals are evaluated as

$$\int_0^\pi \sin \theta' \cos k\theta' d\theta' = \begin{cases} 0, & k = 1, 3, 5, \dots \\ -\frac{2}{k^2 - 1}, & k = 0, 2, 4, \dots \end{cases} \quad (24)$$

(we note that these integrals vanish for all odd values of  $k$ ). As a result, we obtain the following discrete eigenvalue problem

$$i\lambda \sum_{k=0}^{N-1} A_{jk} \alpha_k = \sum_{k=0}^{N-1} (B_{jk} + C_{jk} + D_{jk}) \alpha_k, \quad j = 0, \dots, N-1, \quad (25a)$$

$$\sum_{\substack{k=0 \\ k \text{ even}}}^{N-1} \frac{\alpha_k}{k^2 - 1} = 0 \quad (25b)$$

in which

$$A_{jk} := \cos k\theta_j, \quad j, k = 0, \dots, N-1 \quad (26)$$

is the (invertible) collocation matrix, whereas the matrices  $\mathbf{B}$ ,  $\mathbf{C}$  and  $\mathbf{D}$  correspond to the three terms in operator  $\mathcal{L}$ , cf. (14a). We remark that the terms corresponding to all

values  $k = 0, \dots, N-1$  have to be included in expansion (21), even though their sum might not satisfy constraint (14b), as otherwise the collocation problem is not well posed (i.e., matrix (26) is singular). Constraint (13) is then imposed through the generalized formulation (25).

The entries of matrix  $\mathbf{B}$ , corresponding to the first term in operator  $\mathcal{L}$ , are defined as follows

$$B_{jk} := (\mathbf{v}_0 \cdot \mathbf{t})_{\theta_j} k \sin k\theta_j, \quad j, k = 0, \dots, N-1. \quad (27)$$

The entries of matrix  $\mathbf{C}$ , corresponding to the second term in operator  $\mathcal{L}$ , are defined as follows

$$C_{jk} := \left( \mathcal{C} \int_0^\pi I_2(\theta_j, \theta') d\theta' \right) A_{jk}, \quad j, k = 0, \dots, N-1, \quad (28)$$

where the coefficient is given by an improper integral evaluated using the property (16d) to separate the singular part of the kernel (Hackbusch, 1995)

$$\int_0^\pi I_2(\theta, \theta') d\theta' =: \underbrace{\int_0^\pi \left[ I_2(\theta, \theta') - \frac{\cos \theta}{2\pi} \ln |\theta - \theta'| \right] d\theta'}_{\mathcal{T}(\theta)} + \underbrace{\frac{\cos \theta}{2\pi} \int_0^\pi \ln |\theta - \theta'| d\theta'}_{\mathcal{S}(\theta)}, \quad (29)$$

where  $\mathcal{T}(\theta)$  has a bounded and continuous integrand expression and can be therefore accurately evaluated using the function `sum` from `chebfun` (for  $\theta' \approx \theta$  the integrand is represented in terms of a generalized series expansion), whereas  $\mathcal{S}(\theta)$  can be computed analytically as

$$\mathcal{S}(\theta) = \frac{\cos \theta}{2\pi} [(\pi - \theta) \ln(\pi - \theta) - \theta \ln \theta - \pi], \quad \theta \in [0, \pi]. \quad (30)$$

The entries of matrix  $\mathbf{D}$ , corresponding to the last term in operator  $\mathcal{L}$ , are defined as follows

$$D_{jk} := \mathcal{C} \int_0^\pi I_1(\theta_j, \theta') \cos k\theta' d\theta', \quad j, k = 0, \dots, N-1 \quad (31)$$

which represents the action of a weakly-singular integral operator on trigonometric functions. In the light of the property (16c), they are evaluated similarly to (29) by separating the singular part of the kernel. We thus obtain

$$\begin{aligned} \int_0^\pi I_1(\theta, \theta') \cos(k\theta') d\theta' =: & \underbrace{\int_0^\pi \ln |\theta - \theta'| \left[ \frac{I_1(\theta, \theta')}{\ln |\theta - \theta'|} + \frac{\cos \theta}{2\pi} \right] \cos k\theta' d\theta'}_{\mathcal{T}_k(\theta)} \\ & - \underbrace{\frac{\cos \theta}{2\pi} \int_0^\pi \ln |\theta - \theta'| \cos k\theta' d\theta'}_{\mathcal{S}_k(\theta)}, \end{aligned} \quad (32)$$

where  $\mathcal{T}_k(\theta)$  has a bounded and continuous integrand expression and can be therefore accurately evaluated using the function `sum` from `chebfun` (for  $\theta' \approx \theta$  the integrand is

represented in terms of a generalized series expansion). As regards  $\mathcal{S}_k(\theta)$ , for  $k = 0$ , it is already given in (30). For  $k > 0$ , we obtain

$$\int_0^\pi \ln |\theta - \theta'| \cos(k\theta') d\theta' = \frac{i}{2k} \left\{ e^{ik\theta} [\mathcal{E}_1(ik\theta) - \mathcal{E}_1(ik(\theta - \pi)) + \pi i] - e^{-ik\theta} [\mathcal{E}_1(-ik\theta) - \mathcal{E}_1(ik(\pi - \theta)) - \pi i] \right\}, \quad (33)$$

where  $\mathcal{E}_1(z)$ ,  $z \in \mathbb{C}$ , is the exponential integral defined as the complex extension of the function  $\mathcal{E}_1(x) := \int_x^\infty (e^{-t}/t) dt$ ,  $x > 0$  (Olver *et al.*, 2010). We note that, while the LHS of relation (33) is real-valued, it is evaluated in terms of a combination of complex-valued expressions. Since the exponential integral is multi-valued in the complex plane, care must be taken that its values used in (33) are taken from the same sheath.

The eigenvalue problem (25a) needs to be restricted to eigenfunctions satisfying condition (25b) and this is done with a projection approach. Defining  $\mathbf{u} = [\alpha_0, \dots, \alpha_{N-1}]^T$  and the matrix  $\mathbf{M} := -i \mathbf{A}^{-1}(\mathbf{B} + \mathbf{C} + \mathbf{D})$ , equation (25a) can be expressed as

$$\lambda \mathbf{u} = \mathbf{M} \mathbf{u}. \quad (34)$$

Introducing operator  $\mathbf{b} : \mathbb{R}^N \rightarrow \mathbb{R}$  defined as

$$\mathbf{b} = \left[ 2, 0, -\frac{2}{3}, 0, -\frac{2}{15}, \dots, -\frac{2}{(N-1)^2 - 1}, 0 \right], \quad (35)$$

the constraint (25b) can be expressed as  $\mathbf{b} \mathbf{u} = 0$ . The kernel space of this operator,  $\mathcal{N}(\mathbf{b})$ , thus corresponds to the subspace of functions satisfying condition (25b). The projection onto this subspace is realized by the operator  $\mathcal{P}_{\mathcal{N}(\mathbf{b})} := \mathbf{I} - \mathbf{b}^\dagger \mathbf{b}$ , where  $\mathbf{I}$  is the  $N \times N$  identity matrix and  $\mathbf{b}^\dagger := \mathbf{b}^T (\mathbf{b} \mathbf{b}^T)^{-1} = \mathbf{b}^T / \|\mathbf{b}\|_2$  is the Moore-Penrose pseudo-inverse of the operator  $\mathbf{b}$  (Laub, 2005). Defining the restricted variable  $\mathbf{z} := \mathcal{P}_{\mathcal{N}(\mathbf{b})} \mathbf{u}$ , problem (34) transforms to

$$\lambda \mathbf{z} = \mathcal{P}_{\mathcal{N}(\mathbf{b})} \mathbf{M} \mathcal{P}_{\mathcal{N}(\mathbf{b})}^\dagger \mathbf{z} =: \mathbf{M}_{\mathbf{b}} \mathbf{z}, \quad (36)$$

where  $\mathcal{P}_{\mathcal{N}(\mathbf{b})}^\dagger$  is the Moore-Penrose pseudo-inverse of the projector  $\mathcal{P}_{\mathcal{N}(\mathbf{b})}$ , which can now be solved using standard techniques. We note that the dimension of this problem is  $N - 1$ . An alternative approach to impose constraint (25b) is to frame (25) as a generalized eigenvalue problem (Laub, 2005).

We now offer some comments about the accuracy and validation of the computational approach described above. The accuracy of approximation of singular integrals in (29) and (32) was tested by applying this approach to the integral operator in (6) which has the same singularity structure as  $\mathcal{T}(\theta)$  in (29) and  $\mathcal{T}_k(\theta)$  in (32), and for which an exact formula is available, cf. (3). In addition, an analogous test was conducted for the tangential velocity component given by  $\mathcal{C} \mathbf{t}_\theta \cdot [\int_0^\pi \mathbf{K}(\theta, \theta') d\theta' - W \mathbf{e}_x]$ . Using `maxLength=106` (which controls the length of the Chebyshev series in `chebfun`) resulted in  $L_\infty$  errors of order  $\mathcal{O}(10^{-12})$  which is close to the machine precision. The rather

complicated analytical expression (33) used in  $\mathcal{S}_k(\theta)$ , involving multi-valued functions with branch cuts in the complex plane, was validated by comparing it against a numerical approximation of the weakly-singular integral defining  $\mathcal{S}_k(\theta)$ . With the high precision of the numerical quadratures thus verified, the shape differentiation results in (12) were validated by comparing them against simple forward finite-difference approximations of the shape derivatives. For example, the consistency of the first term on the RHS in (12) was checked by comparing it (as a function of  $\theta$ ) to

$$\epsilon^{-1} \mathcal{C} (\mathbf{n}_{\mathbf{x}^\epsilon} - \mathbf{n}_{\mathbf{x}}) \cdot \left[ \int_{\partial\mathcal{A}} \mathbf{K}(\mathbf{x}(t), \mathbf{x}') ds_{\mathbf{x}'} - W \mathbf{e}_x \right]$$

in the limit of vanishing  $\epsilon$ . In the same spirit, the consistency of the second and third term on the RHS of (12) was verified by perturbing the evaluation point  $\mathbf{x}$  and the contour  $\partial\mathcal{A}$ , respectively. We also checked computationally that the projection formulation (36) of the constrained eigenvalue problem (20) gives essentially the same results as its formulation in terms of a generalized eigenvalue problem (the former approach was in fact found to be somewhat more sensitive to round-off errors owing to the conditioning of the projection operator  $\mathcal{P}_{\mathcal{N}(\mathbf{b})}$ ). The algebraic eigenvalue problem was solved in **Matlab** with the QR and Cholesky methods producing essentially identical results.

Anticipating the results of §4, we now introduce a regularized version of eigenvalue problem (36) in which it is ensured that the coefficients  $\alpha_k$  decay with the wavenumber  $k$  sufficiently rapidly, thus guaranteeing the required regularity of the eigenvectors  $u$ . We introduce the following diagonal operator acting as a low-pass filter

$$F_{jk}^\delta := \begin{cases} \frac{1}{1 + (\delta k)^{2p}}, & j = k, \\ 0, & j \neq k, \end{cases} \quad (37)$$

where  $\delta > 0$  is the cut-off length scale and  $p$  a positive integer, and define  $\mathbf{z}^\delta := \mathbf{F}^\delta \mathbf{z}$ . This filter can be regarded as the discretization of the elliptic operator  $\left[ \text{Id} - (-1)^{p+1} \delta^{2p} \frac{\partial^{2p}}{\partial \theta^{2p}} \right]^{-1}$  in the trigonometric basis. We then obtain from (36)

$$\lambda \mathbf{z}^\delta = \mathbf{F}^\delta \mathbf{M}_{\mathbf{b}} (\mathbf{F}^\delta)^{-1} \mathbf{z}^\delta =: \mathbf{M}_{\mathbf{b}}^\delta \mathbf{z}^\delta, \quad (38)$$

from which the original problem is clearly recovered when  $\delta \rightarrow 0$ . The regularized eigenvectors  $u^\delta$  corresponding to  $\mathbf{z}^\delta$  are therefore guaranteed to be smoother than the original eigenvectors  $u$  (the actual improvement of smoothness depends on the value of  $p$ ). In the next section, among other results, we will study the behavior of solutions to eigenvalue problem (38) for a decreasing sequence of regularization parameters  $\delta$ .

## 4 Computational Results

In this section we first summarize the numerical parameters used in the computations and then present the results obtained by solving eigenvalue problem (38) for different

Figure 1: Eigenvalue spectrum of problem (38) obtained with  $N = 1024$  and  $\delta = \frac{1}{32}$ .

values of the regularization parameter  $\delta$ . All computations were conducted setting  $p = 4$  in the regularization operator (37) and using the resolutions  $N = 64, 128, 256, 512, 1024$  in (21). We allowed the regularization parameter to take a wide range of values  $\delta = 1, \frac{1}{2}, \frac{1}{4}, \dots, \frac{1}{1024}$ . We note that with the smallest values from this range regularization barely affects the eigenvalue problem (38) even when the highest resolutions are used. Therefore, these value may be considered small enough to effectively correspond to the limit  $\delta \rightarrow 0$ .

In our analysis below we will first demonstrate that, for a fixed parameter  $\delta$ , the solutions of the regularized problem (38) converge as the numerical resolution  $N$  is refined. Then, we will study the behavior of the eigenvalues and eigenfunctions as the regularization parameter  $\delta$  is reduced. A typical eigenvalue spectrum obtained by solving problem (38) is shown in figure 1. The fact that the spectrum is symmetric with respect to the lines  $\Re(\lambda) = 0$  and  $\Im(\lambda) = 0$  reflects the Hamiltonian structure of the problem. Given the ansatz for the perturbations introduced in §2, eigenvalues with negative imaginary parts correspond to linearly unstable eigenmodes and we see in figure 1 that there are two such eigenvalues in addition to two eigenvalues associated with linearly stable eigenmodes. We will refer as the first and the second to the eigenvalues with, respectively, the larger and the smaller magnitude. In addition to these four purely imaginary eigenvalues, there is also a large number of purely real eigenvalues covering a segment of the axis  $\Im(\lambda) = 0$  which can be interpreted as the *continuous* spectrum. The spectrum shown in figure 1 was found to be essentially independent of the regularization parameter  $\delta$  and its dependence on the numerical resolution  $N$  is discussed below. In this analysis we will set  $\delta = \frac{1}{32}$ .

The dependence of the four purely imaginary eigenvalues on the resolution  $N$  is shown in figures 2(a-d), where we see that the eigenvalues all converge to well-defined limits. However, as will be discussed below, problem (25) does not admit smooth solutions (eigenvectors) and therefore the convergence of eigenvalues  $\lambda^N$  with  $N$  is only algebraic

rather than spectral. Thus, the numerical approximation error for an eigenvalue  $\lambda$  can be represented as  $|\lambda^N - \lambda| = cN^\beta$  for some  $c > 0$  and  $\beta < 0$ . Using the data from figure 2 to evaluate  $(\lambda^N - \lambda^{2N})$  as a function of the resolution  $N$ , one can estimate the order of convergence using a least-squares fit as  $\beta \approx -1.72$  for the first eigenvalue (both stable and unstable) and  $\beta \approx -0.99$  for the second (both stable and unstable). This confirms that the first eigenvalues converge much faster than the second. The dependence of the purely real eigenvalues on the resolution  $N$  is illustrated in figures 3(a–b). First of all, we notice that the purely real eigenvalues do not appear to converge to any particular limit as  $N$  is increased and instead fill the interval of the axis  $\Im(\lambda) = 0$  with increasing density (figure 3(b)). From figure 3(a) we can infer that the lower and upper bounds of this interval approximately scale with the resolution as

$$\min_i [|\Re(\lambda_i^N)|] \sim N^{-0.22} \quad \text{and} \quad \max_i [|\Re(\lambda_i^N)|] \sim N^{1.04}, \quad i = 1, \dots, N, \quad (39)$$

where  $\lambda_i^N$  denotes the  $i$ -th eigenvalue computed with the resolution  $N$ . All these observations allow us to conclude that the continuous eigenvalue problem (20) has four purely imaginary eigenvalues and a continuous spectrum coinciding with the axis  $\Im(\lambda) = 0$ .

We now move on to discuss the eigenvectors corresponding to the purely imaginary eigenvalues. The linearly unstable and stable eigenvectors are shown as functions of the polar angle  $\theta$  for different resolutions  $N$  in figures 4(a–d). In these figures we only show the real parts of the eigenvectors, since given our ansatz (19) for the perturbation, the imaginary parts do not play any role when the eigenvalues are purely imaginary. Hence, below the term “eigenvector” will refer to  $\Re(u^N(\theta))$ . We note that, as the resolution  $N$  increases, the unstable and stable eigenvectors associated with a given eigenvalue become reflections of each other with respect to the midpoint  $\theta = \pi/2$  with the unstable eigenvectors exhibiting a localized peak near the rear stagnation point ( $\theta = 0$ ) and the stable eigenvectors exhibiting such a peak near the front stagnation point ( $\theta = \pi$ ). In figures 4(a–d) we also observe that, for a fixed regularization parameter  $\delta$ , the numerical approximations  $\Re(u^N(\theta))$  of eigenfunctions converge uniformly in  $\theta$  for increasing  $N$ , although this convergence is significantly slower for points  $\theta$  close to the endpoint opposite to where the eigenvector exhibits a peak. We remark that the same behaviour of spectral approximations to eigenfunctions was also observed by Rozi (1999). The two unstable eigenvectors  $\Re(u_1^N)$  and  $\Re(u_2^N)$  are strongly non-normal with  $\langle \Re(u_1^N), \Re(u_2^N) \rangle_{L_2} / (\|\Re(u_1^N)\|_{L_2} \|\Re(u_2^N)\|_{L_2}) \approx 0.96$ , where  $\langle \cdot, \cdot \rangle_{L_2}$  and  $\|\cdot\|_{L_2}$  are respectively the inner product and the norm in the space  $L_2(0, \pi)$ , when  $\delta = 1/32$  and  $N = 1024$ . Consequently, the two unstable eigenvectors appear quite similar as functions of  $\theta$ , especially near the peak (cf. figures 4(a–b)). On the other hand, the Fourier spectra of their expansion coefficients shown in figures 5(a–b) exhibit quite distinct properties. More specifically, we see that the slope of the Fourier spectra for  $k > 1/\delta$  is quite different in the two cases: it is close to  $-7$  and  $-5$  for the eigenvectors associated with, respectively, the first and second eigenvalue. We emphasize however that the specific slopes are determined by the choice of the parameter  $p$  in the regularizing operator (37) and here we are interested in the relative difference of the slopes in the two

(d)

Figure 2: Dependence of the four purely imaginary eigenvalues on the resolution  $N$  with a fixed regularization parameter  $\delta = \frac{1}{32}$ . The eigenvalues shown in (a) and (b) correspond to the two unstable eigenmodes, whereas those shown in (c) and (d) correspond to the two stable eigenmodes.

Figure 3: Dependence of the purely real eigenvalues on the resolution  $N$  with a fixed regularization parameter  $\delta = \frac{1}{32}$  plotted (a) using the logarithmic scale and (b) within the interval  $[0, 2]$  using the linear scale for the vertical axis. For clarity, only the eigenvalues with positive real parts ( $\Re(\lambda_i^N) > 0$ ) are shown.

cases. Further distinctions between the eigenvectors associated with the first and the second eigenvalue will be elucidated below when discussing their behavior in the limit of decreasing regularization parameter  $\delta$ .

Having established the convergence of the numerical approximations of the eigenfunctions with the resolution  $N$  for a fixed regularization parameter  $\delta$ , we now go on to characterize their behaviour when  $\delta$  is decreased. Unless indicated otherwise, the results presented below were obtained with the resolution  $N = 1024$ . In figures 6(a–b) we show the behavior of the two unstable eigenvectors near the rear and front stagnation points for different values of the regularization parameter  $\delta$ . We see that, as this parameter is decreased, the peak near the rear stagnation point (figure 6(a)) becomes steeper and more localized, especially for the eigenvector associated with the first eigenvalue. Likewise, the oscillation of the unstable eigenvectors near the front stagnation point (figure 6(b)) also becomes more intense and localized as  $\delta$  decreases, although this effect is more pronounced in the case of the eigenvector corresponding to the second eigenvalue. These properties are further characterized in the plots of the Fourier spectra of the two eigenvectors shown in figures 7(a–b) for different values of the regularization parameter  $\delta$ . In these plots it is clear that, as the regularization effect vanishes (corresponding to decreasing values of  $\delta$ ), the point where the slope of the spectrum changes moves towards larger wavenumbers  $k$ . For  $k < 1/\delta$  the approximate slopes of the coefficient spectra are, respectively, 0 and  $-1/8$  for the eigenvectors associated with the first and second eigenvalue (this difference of slopes may explain the different behaviors in the physical space already observed in figure 6(b)). Extrapolating from the trends evident in figures 7(a–b) it can be expected that these slopes will remain unchanged in the limit  $\delta \rightarrow 0$ . With this behaviour of the Fourier coefficients, involving no decay at all for the

Figure 4: Unstable eigenvectors corresponding to the first (a) and second (b) eigenvalue, and stable eigenvectors corresponding to the first (c) and second (d) eigenvalue for different resolutions:  $N = 64$  (green solid line),  $N = 128$  (magenta dotted line),  $N = 256$  (blue dash-dotted line),  $N = 512$  (red dashed line),  $N = 1024$  (thick black solid line) with  $\delta = \frac{1}{32}$ . The eigenvectors are normalized such that  $\sup_{\theta \in [0, \pi]} |\Re(u^N(\theta))| = 1$ .

Figure 5: Fourier coefficient spectra  $|\Re(\alpha_k)|$ ,  $k = 1, \dots, N$ , characterizing the eigenvectors associated with the first (a) and the second (b) eigenvalue for different resolutions:  $N = 64$  (green solid line),  $N = 128$  (magenta dotted line),  $N = 256$  (blue dash-dotted line),  $N = 512$  (red dashed line),  $N = 1024$  (thick black solid line). The spectra of the stable and unstable eigenvectors corresponding to eigenvalues with the same magnitude are identical. The straight blue solid lines have the slopes of  $-7$  (a) and  $-5$  (b).

first eigenvector and a slow decay for the second, expansion (21) does not converge in the limit of  $N \rightarrow \infty$ , indicating that the stable and unstable eigenvectors do not have the form of smooth functions, but rather “distributions”. As regards the nature of their singularity, the slopes observed in figures 7(a–b), i.e.,  $0$  and  $-1/8$ , indicate that the eigenvector associated with the first eigenvalue is consistent with the Dirac delta (whose spectral slope is also  $0$ ), whereas the eigenvector associated with the second eigenvalue is intermediate between the Dirac delta and the Heaviside step function (whose spectral slope is  $-1$ ).

Finally, we go on to discuss the eigenvectors associated with the purely real eigenvalues forming the continuous part of the spectrum. Since, as demonstrated in figure 3, for increasing resolutions  $N$  different eigenvalues are actually computed in the continuous spectrum, there is no sense of convergence with  $N$ . We will therefore analyze here the effect of decreasing the regularization parameter  $\delta$  at a fixed resolution  $N = 1024$ . As above, we will focus on the real parts of the eigenvectors (with the imaginary parts having similar properties). To fix attention, we consider the neutrally-stable eigenvector associated with the eigenvalue  $\lambda \approx 1.0502$ . In figure 8 we show the dependence of  $\Re(u^N(\theta))$  on the polar angle  $\theta$  with  $N = 1024$  and for different values of the regularization parameter  $\delta$ . We observe that as  $\delta$  decreases the oscillations move away from the centre of the domain  $[0, \pi]$  towards the endpoints. The number of oscillations, however, remains approximately constant. The corresponding Fourier coefficient spectra

Figure 6: Dependence of the unstable eigenvectors associated with the first (black solid line) and the second (red dashed line) eigenvalue on the polar angle  $\theta$  near the rear (a) and the front (b) stagnation point for different values of the regularization parameter  $\delta = \frac{1}{32}, \frac{1}{64}, \frac{1}{96}, \frac{1}{128}$  with  $N = 1024$  (smaller values of  $\delta$  correspond to more localized eigenvectors). The eigenvectors are normalized such that  $\sup_{\theta \in [0, \pi]} |\Re(u^N(\theta))| = 1$ .

Figure 7: Fourier coefficient spectra  $|\Re(\alpha_k)|$ ,  $k = 1, \dots, N$ , of the eigenvectors associated with the first (a) and second (b) eigenvalue for different values of the regularization parameter  $\delta = \frac{1}{32}, \frac{1}{64}, \frac{1}{96}, \frac{1}{128}$  with  $N = 1024$  (smaller values of  $\delta$  correspond to the plateau in  $|\Re(\alpha_k)|$  extending to larger wavenumbers). The straight blue solid lines represent the slopes of 0 (a) and  $-1/8$  (b).

Figure 8: Real part of the neutrally-stable eigenvector corresponding to the eigenvalue  $\lambda \approx 1.0502$  computed with the resolution  $N = 1024$  and with different values of the regularization parameter  $\delta = \frac{1}{32}, \frac{1}{64}, \frac{1}{96}, \frac{1}{128}$  (smaller values of  $\delta$  correspond to  $\Re(u^N(\theta))$  exhibiting oscillations closer to the endpoints of the domain). The eigenvectors are normalized such that  $\sup_{\theta \in [0, \pi]} |\Re(u^N(\theta))| = 1$ .

are shown in figures 9(a–d). We see in these plots that the Fourier coefficients increase with  $k$  as  $|\Re(\alpha_k)| \sim k^{3/4}$  when  $k < 1/\delta$  which demonstrates that the neutrally-stable eigenvectors are actually more singular objects than the stable and unstable eigenvectors discussed above. We note that in the regularized regime (i.e., for  $k > 1/\delta$ ) the Fourier coefficient spectrum of the neutrally-stable eigenvectors vanishes with the slope of -7, see figure 7(d). Extrapolating from the trends evident in figures 8 and 9 to the limit  $\delta \rightarrow 0$ , we can anticipate that the neutrally-stable eigenfunctions will have the form of a finite number of oscillations localized in an infinitesimal neighbourhood of the stagnation points  $\theta = 0$  and  $\theta = \pi$ . The number of these oscillations appears to be an increasing function of the eigenvalue magnitude  $|\lambda|$ .

## 5 Discussion

In this section we first provide a simple argument to justify the numerical results obtained in §4 and then make some comparisons with the results of earlier studies. Some properties of the eigenvectors discussed in §4 are consequences of the “degeneracy” of the stability operator (14a). More specifically, knowing the streamfunction field (3) characterizing Hill’s vortex, the coefficient of the derivative term on the RHS in (14a) can be expressed as  $\mathbf{v}_0 \cdot \mathbf{t}_\theta = (\mathcal{C}a^2/5) \sin \theta$  which vanishes at the endpoints  $\theta = 0, \pi$ . To illustrate the effect of this degeneracy we will consider a simplified model problem obtained from (20a) by

Figure 9: Fourier coefficient spectra  $|\Re(\alpha_k)|$ ,  $k = 1, \dots, N$ , of the neutrally-stable eigenvectors  $u^N$  shown in figure 8 for the indicated values of the regularization parameter  $\delta$ . In figure (d) the blue solid lines represent the slopes of  $3/4$  and  $-7$ , respectively, for  $k < 1/\delta$  and for  $k > 1/\delta$ .

dropping the integral terms and rescaling the coefficients, so that we obtain

$$i\lambda w(\theta) = \sin \theta \frac{dw(\theta)}{d\theta}, \quad \theta \in [0, \pi] \quad (40)$$

for some  $w(\theta)$ . We now perform a change of variables  $s = s(\theta)$  defined through  $ds = d\theta / \sin \theta$ , so that

$$s(\theta) = \int_{\pi/2}^{\theta} \frac{d\theta'}{\sin \theta'} = \ln (\csc \theta - \cot \theta), \quad (41)$$

where the lower integration bound was chosen to make the transformation antisymmetric with respect to the midpoint of the interval  $[0, \pi]$ . Transformation (41) has the properties  $\lim_{\theta \rightarrow 0} s(\theta) = -\infty$  and  $\lim_{\theta \rightarrow \pi} s(\theta) = +\infty$ , such that it represents a one-to-one map from the interval  $[0, \pi]$  to the real line. Introducing this change of variables in equation (40), we obtain

$$i\lambda w(s) = \sin \theta \frac{dw(s)}{\sin \theta ds} = \frac{dw(s)}{ds}, \quad s \in \mathbb{R}. \quad (42)$$

It then follows from (41) and (42) that equation (40) admits a continuous spectrum coinciding with the entire complex plane  $\lambda \in \mathbb{C}$  with the eigenfunctions given by  $w(\theta) = e^{i\lambda s(\theta)}$ . When the eigenvalues are restricted to the real line  $\lambda = \lambda_{\text{re}} \in \mathbb{R}$ , the corresponding eigenfunctions  $w(\theta)$  exhibit oscillations with wavelengths decreasing as  $\theta \rightarrow 0, \pi$ , as was also observed in §4 for the neutrally-stable modes, cf. figure 8. On the other hand, for purely imaginary eigenvalues  $\lambda = i\lambda_{\text{im}}$ , where  $\lambda_{\text{im}} \in \mathbb{R}$ , the corresponding eigenfunctions take the form  $w(\theta) = (\csc \theta - \cot \theta)^{-\lambda_{\text{im}}}$  which for  $\lambda_{\text{im}} < 0$  has the properties  $\lim_{\theta \rightarrow 0+} w(\theta) = \infty$  and  $\lim_{\theta \rightarrow \pi-} w(\theta) = 0$  consistent with the singular behaviour of the unstable eigenmodes observed in §4, cf. figures 4 and 6. Thus, one can conclude that the singular structure of the eigenvectors is a consequence of the degeneracy of the coefficient in front of the derivative term in (14a) and some qualitative insights about this issue can be deduced based on the simplified problem (40). We add that similar problems are known to arise in hydrodynamic stability, for example, in the context of the inviscid Rayleigh equation describing the stability of plane parallel flows (Schmid & Hennigson, 2001). In that problem, however, the singularity appears inside the domain giving rise to critical layers with locations dependent on the eigenvalues.

We now return to a remark made in Introduction, namely, that Hill's vortices represent a one-parameter family of solutions parameterized by the constant  $\mathcal{C}$ , or equivalently, by the translation velocity  $W$ , cf. (4). We remark that the stability operator defined in (14a) is linear in  $\mathcal{C}$  which implies that eigenvalues  $\lambda$  (and hence also the growth rates) will be proportional to  $\mathcal{C}$  (or  $W$ ). This is also consistent with the observations made by Moffatt & Moore (1978).

Next we compare our findings with the results of Moffatt & Moore (1978) which concerned essentially the same problem. We remark that these results were verified computationally by Pozrikidis (1986). The exponential growth rate of the unstable perturbations predicted by Moffatt & Moore (1978) was (using our present notation)  $-3W/a = 6/15 = 0.4$  which is in excellent agreement with the first unstable eigenvalue

found here, cf. figure 2(a). Similar agreement was found as regards the structure of the most unstable perturbation — Moffatt & Moore (1978) also found it to have the form of a localized spike at the rear stagnation point (the fact that this spike had a finite width seems related to the truncation of the infinite system of ordinary differential equations). It appears that the second unstable mode, cf. figure 4(b), was undetected by the analysis of Moffatt & Moore (1978) due to its smaller growth rate, cf. figure 2(b).

To close this section, we comment on the continuous part of the spectrum which was reported in §4, cf. figures 1 and 3. Such continuous spectra often appear in the study of infinite-dimensional Hamiltonian, or more generally, non self-adjoint systems, where nontrivial effects may arise from its interaction with the discrete spectrum (Weinstein, 2006). In the present problem, however, the results of Moffatt & Moore (1978) and Pozrikidis (1986) indicate that the observed instability has the form of a purely modal growth which can be completely explained in terms of the discrete spectrum and the associated eigenfunctions. Moreover, this is confirmed by the very good agreement between the growth rate of the instability determined by Moffatt & Moore (1978) and the value of the first unstable eigenvalue obtained in our study. These observations thus allow us to conclude that there is no evidence for any role the continuous spectrum might play in the observed instability mechanism.

## 6 Conclusions

In this study we have considered the linear stability of Hill’s vortex with respect to axisymmetric circulation-preserving perturbations. This was done using the systematic approach of Elcrat & Protas (2013) to obtain an eigenvalue problem characterizing the linearized evolution of perturbations to the shape of the vortex boundary. Recognizing that the Euler equation describing the evolution of discontinuous vorticity distributions gives rise to a *free-boundary* problem, our approach was based on shape differentiation of the contour-dynamics formulation in the 3D axisymmetric geometry (Shariff *et al.*, 2008). As such, it did not involve the simplifications invoked in the earlier studies of this problem by Moffatt & Moore (1978); Fukuyu *et al.* (1994); Rozi (1999) which were related to, e.g., approximate only satisfaction of the kinematic conditions on the vortex boundary. The resulting singular integro-differential operator was approximated with a spectral method in which the integral expressions were evaluated analytically and using `chebfun`. We considered a sequence of regularized eigenvalue problems (38) featuring smooth eigenfunctions for which the convergence of the numerical approximation was established. Then, the original problem was recovered in the limit of vanishing regularization parameter  $\delta$ . Since in the limit  $\delta \rightarrow 0$  the eigenfunctions were found to be distributions, the convergence of this approach with the resolution  $N$  was not very fast, but it did provide a precise characterization of their regularity in terms of the rate of decay of the Fourier coefficients in expansion (21). Following this procedure we showed that the stability operator has four purely imaginary eigenvalues, associated with two unstable and two stable eigenmodes, in addition to a continuous spectrum of

purely real eigenvalues associated with neutrally-stable eigenmodes. The two unstable eigenmodes are distributions in the form of infinitely sharp peaks localized at the rear stagnation point and differ by their degree of singularity. The stable eigenmodes have the form of similar peaks localized at the front stagnation point. On the other hand, the neutrally-stable eigenvectors have the form of “wiggles” concentrated in a vanishing neighbourhood of the two stagnation points with the number of oscillations increasing with the eigenvalue magnitude  $|\lambda|$ .

Our results are consistent with the findings from the earlier studies of this problem by Moffatt & Moore (1978); Fukuyu *et al.* (1994); Rozi (1999). We emphasize that these earlier studies did not, however, solve the complete linear stability problem and only considered the linearized evolution of some prescribed initial perturbation (they can be therefore regarded as evaluating the action of an operator (matrix) on a vector, rather than determining all of its eigenvalues and eigenvectors). These studies did conclude that initial perturbations evolve towards a sharp peak concentrated near the rear stagnation point. Thus, our present findings may be interpreted as sharpening the results of these earlier studies. In particular, excellent agreement was found with the growth rate of the unstable perturbations found by Moffatt & Moore (1978).

The findings of the present study lead to some intriguing questions concerning the initial-value problem for the evolution of Hill’s vortex with a perturbed boundary. It appears that, in the continuous setting without any regularization, this problem may not be well-posed, in the sense that, for generic initial perturbations, the vortex boundary may exhibit the same poor regularity as observed for the unstable eigenvectors in §4 (i.e., be at least discontinuous). While it is possible that the nonlinearity might exert some regularizing effect, this is an aspect of the problem which should be taken into account in its numerical solution. A standard numerical approach to the solution of such problems is the axisymmetric version of the “contour dynamics” method (Pozrikidis, 1986; Wakelin & Riley, 1996; Shariff *et al.*, 2008) in which the discretization of the contour boundary with straight segments or circular arcs combined with an approximation of the singular integrals provide the required regularizing effect. On the other hand, the singular structure of the solution can be captured more readily with higher-order methods, such as the spectral approach developed here.

There is a number of related problems which deserve attention and will be considered in the near future. A natural extension of the questions addressed here is to investigate the stability of Hill’s vortex with respect to non-axisymmetric perturbations, as already explored by Fukuyu *et al.* (1994); Rozi (1999). Another interesting question is to consider the effect of swirl (Moffatt, 1969; Hattori & Hijiya, 2010). Hill’s vortex is a member of the Norbury-Fraenkel family of inviscid vortex rings and their stability remains an open problem. It was argued by Moffatt & Moore (1978) that the highly localized nature of the boundary response of Hill’s vortex to perturbations is a consequence of the presence of a stagnation point. Since the Norbury-Fraenkel vortices other than Hill’s vortex do not feature stagnation points on the vortex boundary, it may be conjectured that in those cases eigenfunctions of the stability operator will be smooth functions of the arclength coordinate. Therefore, in the context of the linear stability problem,

the family of the Norbury-Fraenkel vortex rings may be regarded as a “regularization” of Hill’s vortex analogous and alternative to our approach developed in §3, cf. (37)–(38). The different problems mentioned in this paragraph, except for the effect of swirl, can be investigated using the approach developed by Elcrat & Protas (2013) and also employed in the present study. As regards the stability of Hill’s vortex with swirl, the difficulty stems from the fact that, to the best of our knowledge, there is currently no vortex-dynamics formulation of the type (5) available for axisymmetric flows with swirl. Our next step will be to analyze the stability of the Norbury-Fraenkel vortex rings to axisymmetric perturbations. Finally, it will also be interesting to compare the present findings with the results of the short-wavelength stability analysis of Hattori & Hijiya (2010). In particular, one would like to know if there is any overlap between the two stability analyses and, if so, whether they can produce comparable predictions of the growth rates.

## Acknowledgments

The authors are thankful to Toby Driscoll for helpful advice on a number of `chebfun`-related issues and to Dmitry Pelinovsky for his comments on the singular structure of the eigenfunctions. Anonymous referees provided constructive comments which helped us to improve the paper. B.P. acknowledges the support through an NSERC (Canada) Discovery Grant.
